

**OPTICAL DISC AND  
OPTICAL DISC ADDRESS READING APPARATUS AND  
METHOD**

**5 BACKGROUND OF THE INVENTION**

**1. Field of the Invention**

The present invention relates to an optically rewritable optical disc and to an apparatus and method for reading addresses prewritten to the optical disc.

10

**2. Description of Related Art**

DVD-RAM, CD-RW, and MD are examples of user-recordable optical discs that have become available in the last few years. This type of recordable optical disc has grooves formed along a spiral or plural concentric tracks with a phase change material or magneto-optical material formed on the groove surface. Addresses for specifying a particular location on the disc are also pre-recorded to the tracks using rewritable marks. This type of address is described in Japanese Patent Laid-Open Publication (*kokai*) H8-315426.

Kokai H8-315426 describes providing discontinuities in the grooves and using these discontinuous parts for forming a pattern corresponding to the address signal. A pattern corresponding to the address signal is a binary signal that inverts at each discontinuity, an on/off signal used for generating an ATIP (Absolute Time Pregroove) signal. The discontinuities are therefore used simply as a signal indicating presence or absence.

25

**SUMMARY OF THE INVENTION**

(Technical problem to be solved)

More address values and a method for more efficiently assigning address values is needed in order to create an optical disc with an even higher recording density. In an optical disc according to the related art, however, the discontinuities are nothing more than a trigger signal for signal inversion and  
5 can carry only one piece of information (trigger data). Numerous marks are therefore required.

Furthermore, the approximate location of a track can be detected with the ATIP signal, but the position where recording starts cannot be precisely determined. This means that when appending a new recording after  
10 recording once, or when overwriting data in the middle of a previous recording, new data may be recorded over previously recorded data that is still necessary. Crosstalk also occurs more easily when the track pitch is reduced.

The present invention is directed to a solution for these problems and provides an optical disc wherein discontinuities or modifications are  
15 formed in the grooves and two or more meanings are imparted to the discontinuities or modifications in order to provide address information more efficiently.

A further object of the invention is to provide an optical disc whereby the positioning precision of the recording start point can be increased.

20 A yet further object of the invention is to provide an optical disc enabling the track pitch to be reduced.

A yet further object of the invention is to provide an optical disc that is recordable and playable with full CLV (constant linear velocity) control.

25 A yet further object of the invention is to provide an apparatus and method of simple design for accurately reading address information from an optical disc having address information containing two or more meanings imparted to discontinuities or modifications formed in the grooves.

The invention as described in claim 1 is a rewritable optical disc with a spiral or concentric track comprising:

a groove formed with a sinusoidal wobble along the track;

a sector block disposed along the track;

5 sectors formed by dividing each sector block into a plurality of parts;

a synchronization mark formed in the first sector in each sector block; and

10 positive marks or negative marks formed in sectors other than the first sector in each sector block;

each positive mark being a first groove discontinuity creating a discontinuity of a first width  $W1$  in the track direction of the groove,

15 each negative mark being a second groove discontinuity creating a discontinuity of a second width  $W0$  in the track direction of the groove, and

each synchronization mark being a third groove discontinuity creating a discontinuity of a third width  $Ws$  in the track direction.

20 The invention as described in claim 2 is an optical disc as described in claim 1, wherein the first, second, and third groove discontinuities have a mirror surface.

The invention as described in claim 3 is an optical disc as described in claim 1, wherein the first, second, and third groove discontinuities are formed in maximum amplitude parts of the wobble groove.

25 The invention as described in claim 4 is an optical disc as described in claim 1, wherein the first, second, and third groove discontinuities are formed in the minimum amplitude part of the wobble groove.

The invention as described in claim 5 is an optical disc as described in claim 1, wherein the first, second, and third widths  $W1$ ,  $W0$ , and

Ws are all longer than the longest mark contained in data recorded to a groove and less than or equal to  $1/2$  wobble period.

The invention as described in claim 6 is an optical disc as described in claim 1, wherein the first, second, and third widths W1, W0, and  
5 Ws are all longer than the longest mark contained in data recorded to a groove and less than or equal to  $1/4$  wobble period.

The invention as described in claim 7 is an optical disc as described in claim 1, wherein the ratio between first, second, and third widths W1, W0, and Ws is 1:2:4 where any one of widths W1, W0, and Ws is 1.

10 The invention as described in claim 8 is an optical disc as described in claim 1, wherein the ratio between first, second, and third widths W1, W0, and Ws is 2:1:4.

The invention as described in claim 9 is an optical disc as described in claim 1, wherein the first, second, and third widths W1, W0, and  
15 Ws are two bytes, one byte, and four bytes, respectively.

The invention as described in claim 10 is a rewritable optical disc with a spiral or concentric track comprising:

- a groove formed with a sinusoidal wobble along the track;

- a sector block disposed along the track;

20 sectors formed by dividing each sector block into a plurality of parts;

- a synchronization mark formed in the first sector in each sector block; and

25 positive marks or negative marks formed in sectors other than the first sector in each sector block;

- each positive mark, negative mark, and synchronization mark being formed as a groove top offset portion where the groove is locally offset in a first direction perpendicular to the track direction, a groove bottom offset

portion where the groove is locally offset in a second direction perpendicular to the track direction, or a combination of groove bottom offset portions and groove top offset portions.

The invention as described in claim 11 is an optical disc as  
5 described in claim 10, wherein:

a positive mark is a groove top offset portion;

a negative mark is a groove bottom offset portion; and

a synchronization mark is a combination of a groove top offset  
portion and groove bottom offset portion.

10 The invention as described in claim 12 is an optical disc as  
described in claim 10, wherein the groove bottom offset portions and groove  
top offset portions are disposed at maximum amplitude parts of the wobble  
groove and are offset in a track center direction.

The invention as described in claim 13 is an optical disc as  
15 described in claim 10, wherein groove bottom offset portions and groove top  
offset portions of a synchronization mark are mutually adjacent at  $n+(1/2)$   
wobble cycles (where  $n$  is a positive integer).

The invention as described in claim 14 is an optical disc as  
described in claim 13, wherein  $n$  is 0.

20 The invention as described in claim 15 is a rewritable optical disc  
with a spiral or concentric track comprising:

a groove formed with a sinusoidal wobble along the track;

a sector block disposed along the track;

sectors formed by dividing each sector block into a plurality of

25 parts;

a synchronization mark formed in the first sector in each sector  
block; and

positive marks or negative marks formed in sectors other than the first sector in each sector block;

each positive mark, negative mark, and synchronization mark being formed by a groove ascending-phase inversion part for vertically phase inverting an approximately 1/4 wobble cycle part from a trough in the wobble groove, a groove descending-phase inversion part for vertically phase inverting an approximately 1/4 wobble cycle part from a peak in the wobble groove, or a combination of a groove ascending-phase inversion part and groove descending-phase inversion part.

The invention as described in claim 16 is an optical disc as described in claim 15, wherein a positive mark is formed by a groove ascending-phase inversion part, a negative mark is formed by a groove descending-phase inversion part, and a synchronization mark is formed by a combination of a groove descending-phase inversion part and groove ascending-phase inversion part.

The invention as described in claim 17 is an optical disc as described in claim 15, wherein both ends of said groove descending-phase inversion parts and groove ascending-phase inversion parts are a groove discontinuity.

The invention as described in claim 18 is an optical disc as described in claim 15, wherein both ends of said groove descending-phase inversion parts and groove ascending-phase inversion parts are an abruptly displaced groove.

The invention as described in claim 19 is a rewritable optical disc with a spiral or concentric track comprising:

- a groove formed with a sinusoidal wobble along the track;
- a sector block disposed along the track;

sectors formed by dividing each sector block into a plurality of parts;

a synchronization mark formed in the first sector in each sector block; and

5 positive marks or negative marks formed in sectors other than the first sector in each sector block;

each positive mark, negative mark, and synchronization mark being formed by a groove ascending-rectilinear portion connected to the wobble peak by forming the groove at a trough level from a trough in the wobble groove to an approximately 1/4 wobble cycle portion of the wobble groove, then abruptly changing to a peak level and forming the groove at the peak level in the next 1/4 wobble cycle portion,

10 a groove descending-rectilinear portion connected to the wobble trough by forming the groove at a peak level from a peak in the wobble groove to an approximately 1/4 wobble cycle portion of the wobble groove, then abruptly changing to a trough level and forming the groove at the trough level in the next 1/4 wobble cycle portion, or

15 a combination of a groove descending-rectilinear portion and groove ascending-rectilinear portion.

20 The invention as described in claim 20 is an optical disc as described in claim 19, wherein a positive mark is formed by a groove ascending-rectilinear portion, a negative mark is formed by a groove descending-rectilinear portion, and a synchronization mark is formed by a combination of a groove descending-rectilinear portion and groove ascending-rectilinear portion.

25 The invention as described in claim 21 is an optical disc as described in claim 19, wherein each positive mark, negative mark, and synchronization mark is formed by said groove ascending-rectilinear portion

being repeated for a plurality of cycles of the wobbled groove, said groove descending-rectilinear portion being repeated for a plurality of cycles of the wobbled groove, or said combination of a groove descending-rectilinear portion and groove ascending-rectilinear portion being repeated for a plurality of cycles  
5 of the wobbled groove.

The invention as described in claim 22 is an optical disc as described in claim 21, wherein each positive mark is formed by said groove ascending-rectilinear portion being repeated for a plurality of cycles of the wobbled groove,

10 each negative mark is formed by said groove descending-rectilinear portion being repeated for a plurality of cycles of the wobbled groove, and

each synchronization mark is formed by said combination of a groove descending-rectilinear portion and groove ascending-rectilinear portion  
15 being repeated for a plurality of cycles of the wobbled groove.

The invention as described in claim 23 is an address reading apparatus for detecting synchronization marks, positive marks, and negative marks contained in an optical disc as described in claim 1 and accumulating 1 and 0 data obtained from positive marks and negative marks dispersedly  
20 contained in one sector block to read said sector block address, comprising:

an optical head (2) for emitting a laser beam to a track of the optical disc and detecting reflected light by means of two photodetectors separated along the track direction;

a subtracter (4) for getting a difference of signals from the two  
25 photodetectors and generating a difference signal;

a filter (6) for removing a wobble frequency component of a wobbled track and generating a groove discontinuity pulse;

a discriminator (12) for detecting a groove discontinuity pulse width and discriminating each synchronization mark, positive mark, and negative mark based on said width to generate a synchronization mark signal, positive mark signal, and negative mark signal; and

5 a demodulator (14) for generating 1s and 0s according to each positive mark signal and negative mark signal contained between one synchronization mark signal and a next synchronization mark signal.

The invention as described in claim 24 is an address reading method for detecting synchronization marks, positive marks, and negative  
10 marks contained in an optical disc as described in claim 1 and accumulating 1 and 0 data obtained from positive marks and negative marks dispersedly contained in one sector block to read said sector block address, comprising:

emitting a laser beam to a track of the optical disc and detecting reflected light by means of two photodetectors separated along the track  
15 direction;

getting a difference of signals from the two photodetectors and generating a difference signal;

removing a wobble frequency component of a wobbled track and generating a groove discontinuity pulse;

20 detecting a groove discontinuity pulse width and discriminating each synchronization mark, positive mark, and negative mark based on said width to generate a synchronization mark signal, positive mark signal, and negative mark signal; and

generating 1s and 0s according to each positive mark signal and  
25 negative mark signal contained between one synchronization mark signal and a next synchronization mark signal.

The invention as described in claim 25 is an address reading apparatus for detecting synchronization marks, positive marks, and negative

marks contained in an optical disc as described in claim 10 and accumulating 1 and 0 data obtained from positive marks and negative marks dispersedly contained in one sector block to read said sector block address, comprising:

an optical head (2) for emitting a laser beam to a track of the optical disc and detecting reflected light by means of two photodetectors separated along the track direction;

a subtracter (4) for getting a difference of signals from the two photodetectors and generating a difference signal;

a filter (6) for removing a wobble frequency component of a wobbled track and generating a groove bottom offset portion pulse in a negative direction and a groove top offset portion pulse in a positive direction;

discriminators (52, 54, 12) for discriminating each synchronization mark, positive mark, and negative mark based on said groove top offset portion pulse, groove bottom offset portion pulse, and groove bottom offset portion pulse and groove top offset portion pulse pair to generate a positive mark signal, negative mark signal, and synchronization mark signal; and

a demodulator (14) for generating 1s and 0s according to each positive mark signal and negative mark signal contained between one synchronization mark signal and a next synchronization mark signal.

The invention as described in claim 26 is an address reading method for detecting synchronization marks, positive marks, and negative marks contained in an optical disc as described in claim 10 and accumulating 1 and 0 data obtained from positive marks and negative marks dispersedly contained in one sector block to read said sector block address, comprising:

emitting a laser beam to a track of the optical disc and detecting reflected light by means of two photodetectors separated along the track direction;

getting a difference of signals from the two photodetectors and  
generating a difference signal;

removing a wobble frequency component of a wobbled track and  
generating a groove bottom offset portion pulse in a negative direction and a  
5 groove top offset portion pulse in a positive direction;

discriminating each synchronization mark, positive mark, and  
negative mark based on said groove top offset portion pulse, groove bottom  
offset portion pulse, and groove bottom offset portion pulse and groove top  
offset portion pulse pair to generate a positive mark signal, negative mark  
10 signal, and synchronization mark signal; and

generating 1s and 0s according to each positive mark signal and  
negative mark signal contained between one synchronization mark signal and  
a next synchronization mark signal.

The invention as described in claim 27 is an address reading  
15 apparatus for detecting synchronization marks, positive marks, and negative  
marks contained in an optical disc as described in claim 15 and accumulating 1  
and 0 data obtained from positive marks and negative marks dispersedly  
contained in one sector block to read said sector block address, comprising:

an optical head (2) for emitting a laser beam to a track of the  
20 optical disc and detecting reflected light by means of two photodetectors  
separated along the track direction;

a subtracter (4) for getting a difference of signals from the two  
photodetectors and generating a difference signal;

a filter (6) for removing a wobble frequency component of a  
25 wobbled track and generating a groove descending-phase inversion part pulse  
in a negative direction and a groove ascending-phase inversion part pulse in a  
positive direction;

discriminators (52, 54, 12) for discriminating each synchronization mark, positive mark, and negative mark based on said groove ascending-phase inversion part pulse, groove descending-phase inversion part pulse, and groove descending-phase inversion part pulse and groove ascending-phase inversion part pulse pair to generate a positive mark signal, negative mark signal, and synchronization mark signal; and

a demodulator (14) for generating 1s and 0s according to each positive mark signal and negative mark signal contained between one synchronization mark signal and a next synchronization mark signal.

10 The invention as described in claim 28 is an address reading method for detecting synchronization marks, positive marks, and negative marks contained in an optical disc as described in claim 15 and accumulating 1 and 0 data obtained from positive marks and negative marks dispersedly contained in one sector block to read said sector block address, comprising:

15 emitting a laser beam to a track of the optical disc and detecting reflected light by means of two photodetectors separated along the track direction;

getting a difference of signals from the two photodetectors and generating a difference signal;

20 removing a wobble frequency component of a wobbled track and generating a groove descending-phase inversion part pulse in a negative direction and a groove ascending-phase inversion part pulse in a positive direction;

discriminating each synchronization mark, positive mark, and negative mark based on said groove ascending-phase inversion part pulse, groove descending-phase inversion part pulse, and groove descending-phase inversion part pulse and groove ascending-phase inversion part pulse pair to

generate a positive mark signal, negative mark signal, and synchronization mark signal; and

generating 1s and 0s according to each positive mark signal and negative mark signal contained between one synchronization mark signal and a next synchronization mark signal.

The invention as described in claim 29 is an address reading apparatus for detecting synchronization marks, positive marks, and negative marks contained in an optical disc as described in claim 19 and accumulating 1 and 0 data obtained from positive marks and negative marks dispersedly contained in one sector block to read said sector block address, comprising:

an optical head (2) for emitting a laser beam to a track of the optical disc and detecting reflected light by means of two photodetectors separated along the track direction;

a subtracter (4) for getting a difference of signals from the two photodetectors and generating a difference signal;

a filter (6) for removing a wobble frequency component of a wobbled track and generating a groove descending-rectilinear portion pulse in a negative direction and a groove ascending-rectilinear portion pulse in a positive direction;

discriminators (52, 54, 12) for discriminating each synchronization mark, positive mark, and negative mark based on said groove ascending-rectilinear portion pulse, groove descending-rectilinear portion pulse, and groove descending-rectilinear portion pulse and groove ascending-rectilinear portion pulse pair to generate a positive mark signal, negative mark signal, and synchronization mark signal; and

a demodulator (14) for generating 1s and 0s according to each positive mark signal and negative mark signal contained between one synchronization mark signal and a next synchronization mark signal.

The invention as described in claim 30 is an address reading method for detecting synchronization marks, positive marks, and negative marks contained in an optical disc as described in claim 19 and accumulating 1 and 0 data obtained from positive marks and negative marks dispersedly contained in one sector block to read said sector block address, comprising:

emitting a laser beam to a track of the optical disc and detecting reflected light by means of two photodetectors separated along the track direction;

getting a difference of signals from the two photodetectors and generating a difference signal;

removing a wobble frequency component of a wobbled track and generating a groove descending-rectilinear portion pulse in a negative direction and a groove ascending-rectilinear portion pulse in a positive direction;

discriminating each synchronization mark, positive mark, and negative mark based on said groove ascending-rectilinear portion pulse, groove descending-rectilinear portion pulse, and groove descending-rectilinear portion pulse and groove ascending-rectilinear portion pulse pair to generate a positive mark signal, negative mark signal, and synchronization mark signal; and

generating 1s and 0s according to each positive mark signal and negative mark signal contained between one synchronization mark signal and a next synchronization mark signal.

The invention as described in claim 31 is an address reading apparatus for detecting synchronization marks, positive marks, and negative marks contained in an optical disc as described in claim 21 and accumulating 1 and 0 data obtained from positive marks and negative marks dispersedly contained in one sector block to read said sector block address, comprising:

an optical head (2) for emitting a laser beam to a track of the optical disc and detecting reflected light by means of two photodetectors separated along the track direction;

5 a subtracter (4) for getting a difference of signals from the two photodetectors and generating a difference signal;

a filter (6) for removing a wobble frequency component of a wobbled track and generating a groove descending-rectilinear portion pulse in a negative direction and a groove ascending-rectilinear portion pulse in a positive direction;

10 a first counter (93) for counting a number of groove descending-rectilinear portion pulses in a negative direction contained in one sector;

a second counter (94) for counting a number of groove ascending-rectilinear portion pulses in a positive direction contained in one sector;

15 discriminators (95 to 99) for comparing a first count from the first counter and a second count from the second counter and discriminating each synchronization mark, positive mark, and negative mark according to whether the first count is sufficiently high, the second count is sufficiently high, or the first count and second count are substantially equal to generate a positive  
20 mark signal, negative mark signal, and synchronization mark signal; and

a demodulator (14) for generating 1s and 0s according to each positive mark signal and negative mark signal contained between one synchronization mark signal and a next synchronization mark signal.

The invention as described in claim 32 is an address reading  
25 method for detecting synchronization marks, positive marks, and negative marks contained in an optical disc as described in claim 21 and accumulating 1 and 0 data obtained from positive marks and negative marks dispersedly contained in one sector block to read said sector block address, comprising:

emitting a laser beam to a track of the optical disc and detecting reflected light by means of two photodetectors separated along the track direction;

getting a difference of signals from the two photodetectors and  
5 generating a difference signal;

removing a wobble frequency component of a wobbled track and generating a groove descending-rectilinear portion pulse in a negative direction and a groove ascending-rectilinear portion pulse in a positive direction;

counting a number of groove descending-rectilinear portion  
10 pulses in a negative direction contained in one sector as a first count;

counting a number of groove ascending-rectilinear portion pulses in a positive direction contained in one sector as a second count;

comparing the first count and second count and discriminating each synchronization mark, positive mark, and negative mark according to  
15 whether the first count is sufficiently high, the second count is sufficiently high, or the first count and second count are substantially equal to generate a positive mark signal, negative mark signal, and synchronization mark signal;  
and

generating 1s and 0s according to each positive mark signal and  
20 negative mark signal contained between one synchronization mark signal and a next synchronization mark signal.

The invention as described in claim 33 is an optical disc as described in claim 19, wherein the synchronization mark further has a block mark indicating a sector block starting position.

25 The invention as described in claim 34 is an optical disc as described in claim 33, wherein said block mark is formed by disposing a discontinuity in the track groove.

The invention as described in claim 35 is an optical disc as described in claim 33, wherein said block mark is formed by locally changing a width of the track groove.

5 The invention as described in claim 36 is an optical disc as described in claim 33, wherein said block mark is formed by locally changing wobble amplitude.

The invention as described in claim 37 is an optical disc as described in claim 19, wherein each wobble cycle is formed so that the duty ratio differs according to positive data and negative data.

10 The invention as described in claim 38 is an optical disc as described in claim 19, wherein only one edge of the track groove is wobbled.

(Advantages over the related art)

15 Meaning other than simply identifying the presence or absence of a modification can be imparted to each groove modification by forming groove modifications of multiple different shapes in a wobble groove. More information can therefore be recorded with fewer groove modifications.

An address reader of simple configuration according to the present invention can also accurately and efficiently read dispersed addresses.

## DESCRIPTION OF THE PREFERRED EMBODIMENTS

The preferred embodiments of the present invention are described below with reference to the accompanying figures.

### Embodiment 1

Fig. 1A is a plan view of an optical disc according to a preferred embodiment of the present invention, and Fig. 1B describes the placement of sector blocks. Shown in Fig. 1A are the optical disc substrate 101, header 102 that is preformed when the disc is made, recording area 103 where data can be recorded, and sector 104, which is the data recording unit. Fig. 1B shows a sector block 105 containing a specific number (such as 32) of sectors.

A phase change film is formed on the optical disc substrate 101. Data is recorded to this phase change film by optically changing this phase change film between amorphous and crystalline phases, and signals are read using the difference in reflectivity between amorphous and crystal phase parts.

The relationship between sectors 104 and sector block 105 is described in detail next with reference to Fig. 2A.

In an optical disc according to this embodiment of the invention a track comprises a number of consecutive sector blocks 105. As noted above, each sector block 105 contains 32 sectors 104. Each sector 104 starts with a header 102 followed by a recording area 103 where signals are recorded and reproduced. A sector is 2448 bytes long.

A synchronization mark S is recorded in the header 102 of the first sector 104 in each sector block 105. The start of a sector block 105 can be detected by detecting this synchronization mark S.

A positive mark or negative mark is recorded in the header 102 of the second sector 104 in each sector block 105. A value of 1 is below assumed to be assigned to positive marks and a value of 0 assigned to negative marks. In the example shown in Fig. 2A, a negative mark 0 is recorded to the header 102 of the second sector 104. It is thus possible to assign one bit of information to the header in the second and successive sectors 104 (referred to below as successive sectors).

It is therefore possible to generate 31 bits of information using the synchronization mark S and the following positive marks (1) and negative marks (0) by accumulating these data bits from the headers of the 32 sectors in a sector block 105. Stated another way, 31 bits of information can be dispersed one bit at a time to the 31 sectors 104 in a sector block 105, and a synchronization mark is disposed at the beginning of each sector block 105 so that the start of each sector block 105 can be detected. An address having 0 and 1 bits thus dispersed is referred to herein as a "dispersed address."

These 31 bits include 19 bits of primary data and 12 bits of secondary data. The 19-bit primary data identifies the sector block 105 position. This enables detecting the location of  $(2 \text{ to the } 19\text{th power} =) 524,288$  sector blocks 105. This means that if the address of the first sector block in the optical disc is 0 and the sector block address value increments 1 at each successive

sector block, the value yielded by the 19-bit primary data is the absolute address of each sector block 105, and each sector 104 stores 2048 bytes of data and each sector block 105 thus stores  $65,536 = (2048 * 32)$  bytes, then addresses enabling a maximum 34 gigabytes of data can be assigned using this 19-bit address data.

The 12-bit secondary data is allocated to an error correction code enabling correction if any particular bit in the 19-bit primary data or 12-bit secondary data is dropped because of a disc defect, for example, or is erroneously detected during playback. This could be an error correction code for all 31 data bits. Furthermore, because the sector block 105 address value increments one in each successive sector block 105 and the higher bits can be predicted from a preceding sector block 105, the 12-bit secondary data could be an error correction code for the lower 8-bits.

A dispersed address is described in further detail in Japanese Patent Application H11-343060.

As shown in Fig. 2B, an optical disc 101 according to the present invention has multiple spiral or concentric (spiral in this embodiment) tracks divided into sectors. In the example shown in Fig. 1A sector headers (containing the synchronization mark S, positive mark (1) or negative mark (0)) are aligned along virtual lines in the radial direction of the disc, but the headers do not align in any radial direction in the example shown in Fig. 2B.

As shown in Fig. 3, the tracks are grooves and the space between adjacent tracks, such as the space between groove n and groove n+1, is a land. The lands have a mirror surface. The grooves are wave-shaped wobble grooves. The wobble wave has a frequency of 153 cycles per sector, for example. The wobble period thus corresponds to 16 bytes. If the data is recorded with 8-16 modulation and one clock period is T, the shortest mark is 3T and the longest mark is 14T, and one byte is 16T.

In this embodiment of the invention a positive mark (1) is formed by a discontinuity of width  $W_1$  in the track direction in the first groove, a negative mark (0) is formed by a discontinuity of a width 0 in the track direction in a second groove, and a synchronization mark S is formed by a discontinuity of width  $W_s$  in the track direction in a third groove. These groove discontinuities have a mirror surface such as found in the lands.

The synchronization marks S, positive marks, and negative marks do not need to be aligned in the radial direction of the optical disc. The sector length can therefore be the same at any position on the disc, and full CLV control can be achieved.

Recording start positions can also be precisely determined because recording can start immediately following a groove discontinuity.

Synchronization marks, positive marks, and negative marks can be formed using the groove discontinuities as follows.

Before the grooves are formed the optical disc has a mirror surface coated with a photoresist. The wobble grooves are formed by emitting a laser oscillating perpendicularly to the track while the disc rotates. When the laser is interrupted during groove formation a discontinuity resulting in a synchronization mark S, positive mark (1), or negative mark (0) is formed in the groove with the length of the discontinuity determined by how long laser emission is interrupted. In a preferred embodiment of the invention the synchronization marks S, positive marks (1), and negative marks (0) are formed at the peaks or troughs of the wobble groove, that is, where the amplitude is greatest, in order to make the groove discontinuities easier to detect. A single beam laser can therefore be used to cut the grooves by thus forming the marks in groove discontinuities.

The widths  $W_s$ ,  $W_1$ ,  $W_0$  of the groove discontinuities corresponding to synchronization mark S, positive mark (1), and negative mark (0), respectively, are determined as follows.

5 Mark width is preferably greater than the longest mark in the recorded data (i.e., longer than  $14T$  in the present example) so that recorded data signals that leak into the tracking error signal as noise are not mistakenly recognized as a dispersed address, that is, a signal from a synchronization mark S, positive mark (1), or negative mark (0).

10 Furthermore, the synchronization marks S, positive marks (1), and negative marks (0) are disposed where wobble signal amplitude is greatest. Mark width must therefore be less than  $1/2$  the wobble period and preferably  $1/4$  or less of the wobble period in order to improve detection precision.

15 The width  $W$  of the groove discontinuity corresponding to any synchronization mark S, positive mark (1), or negative mark (0) is therefore

$$14T < W < (\text{wobble period}/2) \quad (1)$$

and preferably

$$14T < W < (\text{wobble period}/4). \quad (2)$$

20 To satisfy these conditions (1) and (2) and enable the widths of the groove discontinuities denoting a synchronization mark S, positive mark (1), or negative mark (0) to be easily identified, the width ratio of these marks is set to 4:2:1, for example. While the ratio of the groove discontinuities could be 4:4:4, groove discontinuities in the third groove corresponding to the marks that are most important to recognize, i.e., synchronization marks S, are preferably 4,  
25 discontinuities corresponding to the positive marks (1) are 2 (or 1), and discontinuities corresponding to the negative marks (0) are 1 (or 2). Yet more specifically, the widths of these groove discontinuities are as follow.

third groove discontinuities (synchronization marks S) = 4 bytes

first groove discontinuities (positive marks (1)) = 2 bytes

second groove discontinuities (negative marks (0)) = 1 byte

It will be noted that in addition to expressing whether or not a groove discontinuity is present, these groove discontinuities also express three different meanings (that is, positive mark (1), negative mark (0), and synchronization mark S) depending upon the length of the groove discontinuity.

Fig. 4 shows a device for reading dispersed addresses such as shown in Fig. 3, and Fig. 5 is a waveform diagram of output signals at important points in the address reader. Referring to Fig. 4, this address reader has an optical head 2, subtracter 4, high pass filter 6, comparator 8, discriminator 12, and demodulator 14. The optical head 2 has a light-emitting element 2c for emitting a laser beam, and photodetectors 2a, 2b offset from each other across the track center. The subtracter 4 obtains the difference of the signals output from photodetectors 2a, 2b, and outputs difference signal Sa (Fig. 5). The high pass filter 6 passes high frequency components and outputs groove discontinuity signal Sb (Fig. 5). The comparator 8 compares the groove discontinuity signal Sb with a specific threshold value Sc supplied from threshold value controller 10 and outputs a binary groove discontinuity signal Sd (Fig. 5). The discriminator 12 then determines if the digitized groove discontinuity signal Sd corresponds to a first groove discontinuity (positive mark (1)), second groove discontinuity (negative mark (0)) or third groove discontinuity (synchronization mark S). The demodulator 14 accumulates the 31 positive marks (1) and negative marks (0) following each synchronization mark S to assemble the dispersed address values into a single continuous address value. The difference signal Sa output from the subtracter 4 is a push-pull signal, and can therefore be used as a tracking error signal.

As shown in Fig. 5 the difference signal Sa describes a sinusoidal wave corresponding to the track wobble. The difference signal Sa

drops to zero wherever a groove discontinuity exists, and the signal level therefore drops to zero for a pulse width determined by the width of the discontinuity. The low frequency wave component (the wobble sine wave) is removed from the groove discontinuity signal Sb output by comparator 8,  
5 which acts as a filter, and groove discontinuity signal Sb therefore contains only pulses from the groove discontinuities. These pulses are compared with a specific threshold value to generate the digital groove discontinuity signal Sd.

Fig. 6 shows the discriminator 12 in detail. The pulse width detector 22 of this discriminator 12 receives the digital groove discontinuity  
10 signal Sd and detects the pulse width therefrom. If the detected pulse width of the groove discontinuity signal Sd is 14T or less, the signal is passed to ignore processor 24 and ignored.

If the detected pulse width of the groove discontinuity signal Sd is 14T or greater and 24T or less, the signal is passed to output-0 processor 26,  
15 which thus recognizes a second groove discontinuity signal and outputs signal Se denoting a 0 (Fig. 5). This signal Se is reset by the next groove discontinuity signal Sd.

If the detected pulse width of the groove discontinuity signal Sd is 24T or greater and 48T or less, the signal is passed to output-1 processor 28,  
20 which thus recognizes a first groove discontinuity signal and outputs signal Sf denoting a 1 (Fig. 5). This signal Sf is reset by the next groove discontinuity signal Sd.

If the detected pulse width of the groove discontinuity signal Sd is 48T or greater and 80T or less, the signal is passed to output-S processor 30,  
25 which thus recognizes a third groove discontinuity signal and outputs signal S denoting the beginning of a sector block. This signal S is reset by the next groove discontinuity signal Sd.

If the pulse width of the detected groove discontinuity signal  $S_d$  is  $80T$  or greater, the signal is passed to ignore processor 32 and ignored. It will be obvious that signal  $S_e$  denoting a 0 corresponds to a negative mark (0), signal  $S_f$  denoting a 1 corresponds to a positive mark (1), and signal  $S$  corresponds to a synchronization mark  $S$ .

Signal  $S_e$  denoting a 0 output from output-0 processor 26, signal  $S_f$  denoting a 1 output from the output-1 processor 28, and signal  $S$  from the output-S processor 30 are output to the demodulator 14, which recognizes the dispersed address as a single address.

It will thus be clear that in addition to detecting whether or not the groove is present, the discriminator 12 generates signals with three different meanings (that is, signal  $S_f$  denoting 1, signal  $S_e$  denoting 0, and signal  $S$  denoting a synchronization mark) based on the length of the groove discontinuity signal.

Fig. 7 shows the configuration of demodulator 14 in detail. An encoder 42 converts signal  $S_e$  to a 1-bit 0 signal and signal  $S_f$  to a 1-bit 1 signal. The encoder 42 outputs to the shift register 44, which converts the 1-bit 0 and 1 signals of the 31-bit serial dispersed address to a parallel address. The latch 46 latches the 31-bit address signal in the shift register 44 at signal  $S$ . A parity coder 48 uses the low 12 bits of the 31 address bits for a parity check code. The error correction processor 50 uses this parity check code for error correction of the high 19 address bits of the 31 address bits. The demodulator 14 thus outputs a 19-bit address for each sector block.

It should be noted that depending on the type of optical disc the grooves may refer to trenches or to the lands between trenches. Note that data can later be written to the mirror surface header 102.

The address reader described above features a simple configuration able to efficiently read dispersed addresses. It will also be noted

that the synchronization marks, positive marks, and negative marks are read using a difference signal and can therefore be easily separated from data signals recorded to the grooves.

Furthermore, forming the synchronization marks, positive marks,  
5 and negative marks within the width of the maximum wobble amplitude prevents an increase in crosstalk between adjacent tracks.

Full CLV control from inside to outside disc circumference can also be achieved because the sectors are formed without changing the sector length between the inside and outside circumference and it is not necessary to  
10 align sector block boundaries in the radial direction of the disc. When the boundaries between the sectors and sector blocks where headers are written are aligned in adjacent tracks concentrated in the radial direction of the disc as they are in a zone CLV disc as shown in Fig. 1A, the optical transmittance of the optical disc recording layer differs greatly between the header areas and  
15 non-header areas. Different transmittance values create no problem when the optical disc has only one recording layer. When the optical disc has two or more recording layers, however, local variations in recording layer transmittance produce crosstalk between top and bottom layers, and different transmittance values are therefore undesirable. An optical disc according to  
20 the present invention as shown in Fig. 2B, however, enables full CLV control, does not require that the headers be substantially aligned in the radial direction of the disc; the headers can therefore be dispersed, and interlayer crosstalk can be reduced in a multilayer optical disc.

Disc capacity can also be increased using full CLV control  
25 compared with zone CLV because unused space can be reduced.

The grooves, synchronization marks, positive marks, and negative marks can also be cut using a single beam.

Furthermore, groove discontinuities are formed in the optical disc described above by interrupting the laser beam used to cut the grooves, but can alternatively be formed as shown in Fig. 8 and Fig. 9 by momentarily shifting the laser beam to form groove offset part 62 or 63. The offset time of the laser is adjusted to control the resulting discontinuities.

It should be noted that the identification marks are disposed at the beginning of each sector in the present embodiment but shall not be limited thereto. The marks could, for example, be detected at the end of the sector.

An optical disc according to the first embodiment described above has groove discontinuities of different lengths formed in the header 102 at the beginning of each sector with each groove discontinuity meaning a synchronization mark S, positive mark (1), or negative mark (0), thereby enabling sector block addresses to be encoded in less space.

Furthermore, an optical disc according to the present invention is suitable as a high density optical disc that is readable and recordable using an approximately 400 nm wavelength laser from the light-emitting element 2c. The reasons for this are described below.

An optical disc according to the present invention is a recordable, readable optical disc having a crystal phase (unrecorded state) phase-change material formed on the disc surface in the grooves. This phase change material is, for example, a germanium-antimony compound or a silver-indium compound. Data is recorded by emitting a laser beam at a specific recording power level to this phase change material to change the crystal phase (unrecorded state) to amorphous phase (recorded state) marks. Reflectivity is different in the crystal phase and amorphous phase parts of the groove. Data can therefore be read by emitting a laser beam at a lower power level, and detecting differences in reflected light from the crystal phase and amorphous phase parts of the groove to reproduce the recorded data. If the laser beam is

in the 830 nm or 650 nm waveband, reflections from the amorphous phase (recorded state) parts will be weaker than reflections from the crystal phase (unrecorded state) parts. Furthermore, reflections from the mirror areas are stronger than reflections from the crystal phase parts. Reflections from the mirror, crystal phase, and amorphous phase parts can thus be ranked as strong, medium, and weak, and the three parts can be easily identified.

If a 400 nm laser is used, however, the order of reflectivity changes: reflection from amorphous phase (recorded state) parts is stronger than reflections from crystal phase (unrecorded state) parts. Reflections from the mirror, crystal phase, and amorphous phase parts are therefore ranked slightly strong, medium, strong, and identifying mirror parts from amorphous phase (recorded) parts becomes difficult. With an optical disc according to the present invention, however, the width of the mirror-surface groove discontinuities is distinctly different from the width of the recording marks, and the groove discontinuities can therefore be easily distinguished from the recording marks.

#### (Embodiment 2)

In an optical disc according to this second embodiment of the invention dispersed addresses are recorded using groove modifications, more specifically using a groove bottom offset 65, a groove top offset 66, and a combination 67 of groove bottom offset 65 and groove top offset 66 as shown in Fig. 10. In the example shown in Fig. 10 a single groove top offset 66 denotes a positive mark (1); a combination 67 containing a groove bottom offset 65 and a groove top offset 66 appearing within a specified time of the groove bottom offset 65 denotes a synchronization mark S; and a groove bottom offset 65 not followed by a groove top offset 66 within a specific time denotes a negative mark (0). The groove bottom offsets and groove top offsets

are generically referred to herein as simply "groove offsets." Any one of these parts 65, 66, 67 can be used as a synchronization mark, positive mark, or negative mark, but combination 67 is preferably used as the synchronization marks, which are detected less frequently. The same applies to the alternative versions of this embodiment described below.

A groove bottom offset 65 is formed by creating a momentary offset toward the track center from a peak in the wobble groove. A groove top offset 66 is formed by creating a momentary offset toward the track center from the bottom of a trough in the wobble groove. A combination 67 is formed by creating a groove bottom offset 65 in a peak and a groove top offset 66 in the adjacent trough of the wobble groove.

Note that the groove bottom offset 65 and groove top offset 66 in a combination 67 shown in Fig. 10 are separated  $1/2$  wobble period, but could be separated  $(n+1/2)$  (where  $n$  is a positive integer) wobble period. Note, further, that the groove bottom offset could be formed as shown in Fig. 9 instead of as in Fig. 8. The groove top offsets could also be formed in the same manner.

Fig. 11 shows an address reader for reading dispersed addresses encoded as shown in Fig. 10, and Figs. 12 to 14 are waveform diagrams of the output signals at major points in the address reader. Like parts in the address reader shown in Fig. 4 and the address reader in Fig. 11 are identified by like reference numerals and further description thereof is omitted below. Shown in Fig. 11 are optical head 2, subtracter 4 outputting difference signal  $S_a$  (Fig. 12), high pass filter 6 for outputting groove discontinuity (offset) signal  $S_b$  (Fig. 13), comparators 52 and 54, discriminator 56, and demodulator 14. Comparator 52 compares groove discontinuity (top offset) signal  $S_b$  with specific first threshold value  $+V_{th}$  (Fig. 13) to output digital groove top offset signal  $S_i$  (Fig. 14). Comparator 54 compares groove discontinuity (bottom

offset) signal  $S_b$  with specific second threshold value  $-V_{th}$  (Fig. 13) to output digital groove bottom offset signal  $S_j$  (Fig. 14). Discriminator 56 detects whether the digitized groove top/bottom offset signals  $S_i$  and  $S_j$  correspond to a first groove offset (positive mark (1)), second groove offset (negative mark (0)), or third groove offset (synchronization mark S). Demodulator 14 compiles the dispersed address into a single continuous address value.

Signal  $S_a(S)$  in Fig. 12 is the difference signal for both groove bottom offset 65 and groove top offset 66 in combination 67; signal  $S_a(0)$  is the difference signal for groove bottom offset 65 only; and signal  $S_a(1)$  is the difference signal for groove top offset 66 only. A negative pulse is produced when there is a downward offset at a peak of the wobble groove, and a positive pulse is generated when there is an upward offset in a trough of the wobble groove.

Waveforms for signals  $S_a(S)$ ,  $S_a(0)$ , and  $S_a(1)$  after removing low frequency components are shown as signals  $S_b(S)$ ,  $S_b(0)$ , and  $S_b(1)$  in Fig. 13.

Signals  $S_i(S)$ ,  $S_j(S)$  in Fig. 14 show the digital pulse signals derived from the positive and negative pulses in signals  $S_b(S)$ ,  $S_b(0)$ , and  $S_b(1)$  shown in Fig. 13. Because signal  $S_b(S)$  contains both positive and negative pulses, a pulse is present in both signals  $S_i(S)$  and  $S_j(S)$ . Because signal  $S_b(0)$  contains only a negative pulse, however, a pulse is present in signal  $S_j(0)$  but not in  $S_i(0)$ . Likewise, because signal  $S_b(1)$  only has a positive pulse, a pulse is present in  $S_i(1)$  but not in  $S_j(1)$ .

The discriminator 56 operates as follows.

If either pulse signal  $S_i$  or  $S_j$  is received and the other pulse signal ( $S_i$  or  $S_j$ ) is then also received within a specific period of time (within 1/2 wobble period), synchronization mark S is detected and signal S indicating the

synchronization mark S is therefore output. This synchronization signal S is held until the next mark is detected.

If pulse signal S<sub>j</sub> is not received within a specific time (within 1/2 wobble period) after pulse signal S<sub>i</sub> is received, positive mark (1) is detected and a "1" signal is output indicating the positive mark (1). This "1" signal is held until the next mark is detected.

If pulse signal S<sub>i</sub> is not received within a specific time (within 1/2 wobble period) after pulse signal S<sub>j</sub> is received, negative mark (0) is detected and a "0" signal is output indicating the negative mark (0). This "0" signal is held until the next mark is detected.

Signals S, 1, and 0 are signals as shown in the bottom two rows of Fig. 5, and are output from the three output lines of the discriminator 56 shown in Fig. 11.

The demodulator 14 thereafter operates in the same way as the demodulator shown in Fig. 7.

In addition to indicating whether there is an offset, the groove bottom offset 65 and groove top offset 66 contain information indicating the direction of the offset. Separate signals S<sub>i</sub> and S<sub>j</sub> can therefore be generated.

Groove bottom offset 65 and groove top offset 66 can also be used to identify three different meanings (S, 0, 1) in 1/2 wobble period.

Crosstalk between adjacent tracks also does not occur because the synchronization marks, positive marks, and negative marks are within the width of a maximum amplitude part of the wobble.

Full CLV control is also possible because the sectors are configured without changing the sector length from the inside circumference to the outside circumference of the optical disc and it is not necessary to align the sector block borders in the radial direction of the disc.

The grooves, synchronization marks, positive marks, and negative marks can also be cut using a single laser beam.

Yet further, because the synchronization marks, positive marks, and negative marks are formed offset from the track center, intermixing of data signals with the synchronization mark, positive mark, and negative mark detection signals is minimal even when data is recorded along the track center.

It is also possible to reliably detect groove offsets when the groove offsets are detected with a push-pull signal because the difference signal is large.

10

(First alternative embodiment)

A first alternative version of the groove modifications in the second embodiment of the invention is described below with reference to Fig. 15 to Fig. 20.

15

While groove bottom offset 65 and groove top offset 66 are used in the embodiment shown in Fig. 10, these are changed to groove descending-phase inversion part 74 and groove ascending-phase inversion part 75 in this first alternative embodiment as shown in Fig. 17. The groove descending-phase inversion part 74 vertically inverts the phase of the sinusoidal wobble wave from the groove peak to the groove trough, that is, an approximately 1/4 phase segment of the wobble period from the groove peak. The groove ascending-phase inversion part 75 similarly vertically inverts the phase of the sinusoidal wobble wave from the groove trough to the groove peak, that is, an approximately 1/4 phase segment of the wobble period from the groove trough.

20

The groove descending-phase inversion and groove ascending-phase inversion parts are together referred to as the groove phase inversion parts.

25

As shown in Fig. 17, a synchronization mark S is expressed by a combination 76 of consecutive groove descending-phase inversion 74 and

groove ascending-phase inversion 75 parts. A negative mark (0) contains only groove descending-phase inversion part 74, and a positive mark (1) contains only groove ascending-phase inversion part 75. The ends of the 1/4 wobble period segments can be discontinuities in the groove as indicated in Fig. 16 or sudden displacements in the groove as shown in Fig. 16.

These marks can be read with an address reader as shown in Fig. 11.

Fig. 18 shows the difference signals for the groove phase inversions corresponding to the three marks shown in Fig. 17. These difference signals are output from the subtracter 4. As will be known from difference signal  $S_a(S)$ , a difference signal that drops abruptly to the right is obtained where the phase inverts and there is an abrupt top-to-bottom change in the groove, and a difference signal that rises abruptly to the right is obtained where the phase inverts and there is an abrupt bottom-to-top change in the groove.

Fig. 19 shows the difference signal after it passes the high pass filter 6. A difference signal that drops abruptly to the right appears as a negative pulse, and a difference signal that rises abruptly to the right appears as a positive pulse.

Fig. 20 shows signal  $S_i$  as the digitized version of the positive pulse output by comparator 52, and signal  $S_j$  as the digitized version of the negative pulse output by comparator 54.

Discriminator 56 operates as follows in this case.

If either pulse signal  $S_i$  or  $S_j$  is received and the other pulse signal ( $S_i$  or  $S_j$ ) is then also received within a first specific period of time (within the wobble period), synchronization mark  $S$  is detected and signal  $S$  indicating the synchronization mark  $S$  is therefore output. This synchronization signal  $S$  is held until the next mark is detected.

If a second pulse signal  $S_i$  is received within a second specific time (within  $1/2$  wobble period) after a first pulse signal  $S_i$  is received, positive mark (1) is detected and a "1" signal is output indicating the positive mark (1). The further condition that pulse signal  $S_j$  is not detected between the first and  
5 second pulse signals  $S_i$  can also be applied. This "1" signal is held until the next mark is detected.

If a second pulse signal  $S_j$  is received within a second specific time (within  $1/2$  wobble period) after a first pulse signal  $S_j$  is received, negative mark (0) is detected and a "1" signal is output indicating the negative mark (0).  
10 The further condition that pulse signal  $S_i$  is not detected between the first and second pulse signals  $S_j$  can also be applied. This "0" signal is held until the next mark is detected.

Subsequent signal processing is handled by the demodulator 14 as described above.

15 In addition to indicating whether there is a phase inversion, the groove descending-phase inversion 74 and groove ascending-phase inversion 75 parts contain information indicating the inversion direction. Separate signals  $S_i$  and  $S_j$  can therefore be generated.

Groove descending-phase inversion part 74 and groove  
20 ascending-phase inversion part 75 can also be used to identify three different meanings (S, 0, 1) in one wobble period.

Crosstalk between adjacent tracks also does not occur because the synchronization marks, positive marks, and negative marks are within the width of the maximum amplitude part of the wobble.

25 Full CLV control is also possible because the sectors are configured without changing the sector length from the inside circumference to the outside circumference of the optical disc and it is not necessary to align the sector block borders in the radial direction of the disc.

The grooves, synchronization marks, positive marks, and negative marks can also be cut using a single laser beam.

Furthermore, because the phase inverts where wobble amplitude is greatest, the locations of the synchronization mark S, positive mark (1), or negative mark (0) can be detected with good precision.

It should be noted that the groove descending-phase inversion part 74 and groove ascending-phase inversion part 75 could also be detected by detecting the wobble phase. This results in a greater improvement in the S/N ratio than does detecting the phase inversion edge.

(Second alternative embodiment)

A second alternative version of the groove modifications in the second embodiment of the invention is described below with reference to Fig. 21 to Fig. 25.

While groove bottom offset 65 and groove top offset 66 are used in the embodiment shown in Fig. 10, these are changed in this second alternative version of the second embodiment to descending rectilinear groove part 83 and ascending rectilinear groove part 84. There is an abrupt rectilinear drop from the peak to the trough of the sinusoidally wobbled groove in the descending rectilinear groove part 83. That is, the groove is formed at the peak level for 1/4 wobble cycle from the groove peak, the level then drops abruptly to the trough level, and the groove is then formed at the trough level for the next approximately 1/4 wobble cycle, connecting to the groove trough. In ascending rectilinear groove part 84 there is an abrupt rectilinear rise from the trough to the peak of the sinusoidally wobbled groove. That is, the groove is formed at the trough level through the 1/4 wobble cycle from the groove trough, the level then rises abruptly to the peak level, and the groove is then formed at the peak level in the next approximately 1/4 wobble cycle, connecting to the

groove peak. These rectilinear descending and ascending groove parts are referred to herein as the rectilinear groove parts. Furthermore, a wobble wave containing a rectilinear groove part, groove phase inversion, or groove offset part is referred to as a modified wobble wave.

5           As shown in Fig. 22, a synchronization mark S is expressed by a combination 85 of descending rectilinear groove part 83 and ascending rectilinear groove part 84, a negative mark (0) is recorded using only descending rectilinear groove part 83, and a positive mark (1) is recorded using only ascending rectilinear groove part 84. Fig. 21 shows a descending  
10 rectilinear groove part 83 in detail.

          These marks can be read using an address reader as shown in Fig. 11.

          Fig. 23 shows the difference signal for rectilinear groove parts corresponding to the three marks shown in Fig. 22. These difference signals  
15 are output by the subtracter 4 shown in Fig. 11. As will be known from difference signal  $S_a(S)$ , a difference signal that drops abruptly to the right is obtained where there is a steeper change outwardly from top-to-bottom in the rectilinear groove part, and a difference signal that rises abruptly to the right is obtained where there is a steeper change inwardly from bottom-to-top in the  
20 rectilinear groove part.

          Fig. 24 shows the difference signal after it passes high pass filter 6. A difference signal that drops abruptly to the right appears as a negative pulse, and a difference signal that rises abruptly to the right appears as a positive pulse.

25           Fig. 25 shows signal  $S_i$  as the digitized version of the positive pulse output by comparator 52, and signal  $S_j$  as the digitized version of the negative pulse output by comparator 54.

          Discriminator 56 operates as follows in this case.

If either pulse signal  $S_i$  or  $S_j$  is received and the other pulse signal ( $S_i$  or  $S_j$ ) is then also received within a first specified time (within the wobble period), synchronization mark  $S$  is detected and signal  $S$  indicating the synchronization mark  $S$  is therefore output. This synchronization signal  $S$  is held until the next mark is detected.

If pulse signal  $S_j$  is not received within a specified time (within the wobble period) after pulse signal  $S_i$  is received, positive mark (1) is detected and a "1" signal is output indicating the positive mark (1). This "1" signal is held until the next mark is detected.

If pulse signal  $S_i$  is not received within a specified time (within the wobble period) after pulse signal  $S_j$  is received, negative mark (0) is detected and a "0" signal is output indicating the negative mark (0). This "0" signal is held until the next mark is detected.

The demodulator 14 thereafter operates as described above.

In addition to indicating whether there is a rectilinear part in the wobble groove, the descending rectilinear groove part 83 and ascending rectilinear groove part 84 contain information indicating the direction. Separate signals  $S_i$  and  $S_j$  can therefore be generated.

The descending rectilinear groove part 83 and ascending rectilinear groove part 84 can also be used to identify three different meanings ( $S$ , 0, 1) in a wobble period.

Crosstalk between adjacent tracks also does not occur because the synchronization marks, positive marks, and negative marks are within the width of the maximum amplitude part of the wobble.

Full CLV control is also possible because the sectors are configured without changing the sector length from the inside circumference to the outside circumference of the optical disc and it is not necessary to align the sector block borders in the radial direction of the disc.

The grooves, synchronization marks, positive marks, and negative marks can also be cut using a single laser beam.

Furthermore, because the rectilinear part is formed across the peak amplitude part of the wobble, the position of the synchronization mark, positive mark, or negative mark can be highly precisely detected.

Yet further, because the zero cross point of the sinusoidal wobble wave and the zero cross point of the rectilinear part are the same, the clock signal will not be disrupted at a mark when the clock signal is extracted from the wobble.

It should be noted that in this second embodiment the location of the groove modification differs in S, 0, and 1 marks, and the location where recording can start therefore also differs. An additional mark is needed in order to unify the positions from which recording can start. For example, a groove discontinuity 68 can be added as shown in Fig. 26 to the embodiment shown in Fig. 10. More specifically, the recording start positions can be unified by starting recording after detecting a groove discontinuity 68.

(Third alternative embodiment)

A third alternative version of the groove modifications in the second embodiment of the invention is described below with reference to Fig. 27 to Fig. 31.

The embodiment shown in Fig. 22 uses one modified wobble wave to record one mark. More specifically, one descending rectilinear groove part 83 denotes one negative mark (0), one ascending rectilinear groove part 84 denotes one positive mark (1), and one rectilinear pair 85 (containing one descending rectilinear groove part 83 and one ascending rectilinear groove part 84) denotes a synchronization mark S.

In the third alternative embodiment shown in Fig. 27, however, a succession of modified wobble waves are used. That is, a specific plural number of wobble wave cycles (such as 32 cycles) is included in the header 102 of one sector 104 included in the sector block 105 shown in Fig. 2. To record a synchronization mark, the rectilinear pair 85 is repeated to occupy plural cycles (such as 32 cycles in the header 102 as shown in the top row in Fig. 27. To record a negative mark (0), the descending rectilinear groove part 83 is repeated plural times in plural wobble wave cycles (e.g., 32 cycles) in the header 102 as shown in the middle row in Fig. 27. To record a positive mark (1), the ascending rectilinear groove part 84 is repeated plural times in plural wobble wave cycles (e.g., 32 cycles) in the header 102 as shown in the bottom row in Fig. 27.

In yet another embodiment the modified wobble wave is recorded not just in the header 102 but throughout all sectors 104 containing a recording area 103. For example, if there are 153 wobble wave cycles in one sector, the modified wobble wave is recorded to all 153 cycles of the wobble wave.

More specifically, a modified wobble wave containing the rectilinear pair 85 is recorded for 153 continuous cycles throughout the first sector in the sector block 105, and each rectilinear pair 85 is used to represent synchronization data S. If a negative value 0 is to be recorded to the remaining sectors following the first sector in the block, a modified wobble wave containing the descending rectilinear groove part 83 is recorded for 153 continuous cycles throughout each sector. Likewise, if a positive value 1 is to be recorded to the remaining sectors, a modified wobble wave containing the ascending rectilinear groove part 84 is recorded for 153 continuous cycles throughout the sector.

It will be apparent that it is not necessary to repeat the modified wobble wave throughout the sector, and it can be repeated a certain plural

number of cycles at any part of the sector. Furthermore, the plural cycles in which the modified wobble wave is recorded can be non-contiguous, such as every other cycle. By thus inserting space between the cycles containing the modified wobble wave other information can also be recorded by measuring  
5 the gap between the cycles.

By thus recording data to the wobble waves using modified wobble waves as described above it is not necessary to use track space to record the synchronization mark S, positive mark (1), or negative mark (0), and data can be extracted by observing the shape of the modified wobble waves of  
10 the track. It is therefore not necessary to insert the synchronization mark S, positive mark (1), or negative mark (0) to the header 102 or other specific location, and they can be recorded at a desirably location.

A discontinuity 86 is also recorded in the first wobble wave as shown in the top row in Fig. 27 in order to make detecting the start of the  
15 sector block easier and more reliable. This discontinuity 86 can be disposed to the peak of the wobble wave as shown in Fig. 27 or in the trough (that is, at a peak amplitude part of the wave), or at the zero cross point of the descending rectilinear groove part 83 or ascending rectilinear groove part 84 (that is, at the minimum amplitude part of the wave). The discontinuity 86 is preferably  
20 disposed at the zero cross point because the discontinuity 86 will then not produce unnecessary noise during wobble wave frequency detection. It will be further noted that this location of discontinuities also applies to the discontinuities described in the first embodiment above.

It will be noted that the discontinuity 86 in Fig. 27 is formed by  
25 interrupting the track groove and overwriting data to the discontinuity 86 is therefore difficult. This is because light reflection differs greatly depending on whether or not the groove is present and the discontinuity 86 behaves like noise in the playback signal. In the present embodiment, therefore, the area

containing such a discontinuity 86 (such as block 85) is used as a VFO recording area. A VFO recording area is an area where a monotone VFO signal is recorded for generating the PLL used to playback the data recorded after the VFO recording area. Some variation in such external noise simply appears as local jitter in a VFO area, and will not directly produce an error. Furthermore, frequency separation of noise caused by the discontinuity 86 is also possible because the VFO signal is a monotone signal.

Fig. 31 is a block diagram of a reader for reading a modified wobble wave as shown in Fig. 27.

The reader shown in Fig. 31 comprises a rectilinear wave detector 90, discontinuity detector 91, and distribution detector 92. The rectilinear wave detector 90 uses the major parts of the address reader shown in Fig. 11. Waveforms of the signals at major points in the rectilinear wave detector 90 are shown in Fig. 28, Fig. 29, and Fig. 30.

Fig. 28 shows the difference signals for the three modified wobble waves shown in Fig. 27. These difference signals are output by the subtracter 4 shown in Fig. 31. This subtracter 4 operates as described with reference to Fig. 11.

Fig. 29 shows the difference signals after passing the high pass filter 6. A difference signal that drops abruptly to the right appears as a negative pulse, and a difference signal that rises abruptly to the right appears as a positive pulse.

Fig. 30 shows signal  $S_i$  as the digital version of the positive pulse output by comparator 52, and signal  $S_j$  as the digital version of the negative pulse output by comparator 54. In a modified wobble wave containing repeated rectilinear pairs 85, a pulse appears in both signals  $S_i$  and  $S_j$ . These pulses appear once per cycle in the modified wobble wave.

Operation when the modified wobble wave has 153 cycles per sector is described next. In the first sector (the sector containing the synchronization mark S) there are 153 pulses in signal Si and 153 pulses in signal Sj. If the following sector records 0 data (negative mark (0)) there are no pulses in signal Si and 153 pulses in signal Sj. If the following sector records 1 data (positive mark (1)) there are 153 pulses in signal Si and no pulses in signal Sj. Note that due to noise and other factors the actual number of pulses may vary.

The discontinuity detector 91 shown in Fig. 31 uses the major parts of the address reader shown in Fig. 4. As described with reference to Fig. 5, a pulse is output when a discontinuity 86 is detected. Note that the subtracter 4 disposed in discontinuity detector 91 can be changed to an adder. When a subtracter is used the discontinuity 86 can only be detected when it is near a wobble wave peak, but when an adder is used discontinuity 86 can be detected near the peak and near the zero cross.

The distribution detector 92 shown in Fig. 31 is described next.

The distribution detector 92 comprises pulse counters 93 and 94, comparators 95, 96, 97, sector synchronization counter 98, and latch 99. Pulse counters 93 and 94 count the number of pulses in signals Si and Sj, respectively. Pulse counter 93 outputs the accumulated count to input b of comparators 95, 96, 97. If  $a > b$  (where a is the count applied to input a, and b is the count applied to input b) and the difference is preferably sufficiently great (that is,  $a \gg b$ ), comparator 95 outputs high. If  $a < b$  and the difference is preferably sufficiently great (that is,  $a \ll b$ ), comparator 96 outputs high. If  $a \approx b$  and the difference is preferably sufficiently small, comparator 97 outputs high.

These high signals are applied to the latch 99. If a high signal is received from comparator 95, latch 99 outputs a 1 indicating a positive mark (1). This 1 signal is held until data for the next sector is detected. If the latch 99

receives a high from comparator 96, latch 99 outputs a 0 signal indicating a negative mark (0). This 0 signal is held until data for the next sector is detected. If a high from comparator 97 is detected, latch 99 outputs an S signal indicating a synchronization mark S. This S signal is held until data for the next  
5 sector is detected.

The sector synchronization counter 98 counts the number of cycles in the synchronization signal (the same number of cycles as the wobble wave, but the wobble wave contains noise and the number is not stable). The synchronization signal is generated by a PLL circuit from the detected wobble  
10 signal, for example. First, the count is reset to zero at the discontinuity detection pulse from the discontinuity detector 91. The number of pulses in the synchronization signal, that is, the synchronization pulses, is then counted. The wobble wave has 153 cycles per sector in the present embodiment as noted above. A reset signal is therefore output to the pulse counters 93 and 94  
15 and latch 99 every time 153 pulses are counted, and the pulse counters 93 and 94 are reset.

The distribution detector 92 compares the number of pulses in signal  $S_i$  in one sector with the number of pulses in signal  $S_j$ . If the number of signal  $S_i$  pulses is sufficiently greater than the number of signal  $S_j$  pulses, comparator 95 outputs high. Conversely, if the number of signal  $S_j$  pulses is  
20 sufficiently greater than the number of signal  $S_i$  pulses, comparator 96 outputs high. If the number of  $S_i$  pulses and  $S_j$  pulses is almost equal, comparator 97 outputs high. The latch 99 latches a high signal from any of comparators 95, 96, 97 and appropriately outputs a 1 or 0 signal. The sector synchronization  
25 counter 98 is reset by an S signal.

Subsequent signal processing is handled by the demodulator 14 as described above.

The 1, 0, and S signals can be detected more accurately by thus repeating the modified wobble wave. Furthermore, adverse effects of the wobble wave on the synchronization signal that must be detected can be minimized if a modified wobble wave containing a rectilinear component as  
5 described above is included in the modified wobble wave.

(Fourth alternative embodiment)

Fig. 32 shows the major components of a fourth alternative embodiment. In the embodiment shown in Fig. 32 the length of the positive  
10 amplitude parts and negative amplitude parts of the wobble wave differ so that the duty ratio can be changed without changing the wobble frequency. More specifically, in Fig. 32 the length of the negative amplitude part 180 of the wobble wave is longer than the positive amplitude part, and the length of the positive amplitude part 181 is longer than the negative amplitude part. The  
15 wobble is thus formed so that this part 180 is longer in a negative mark (0) and part 181 is longer in a positive mark (1) as shown in Fig. 32. It is therefore not necessary to differentiate the playback signal when discriminating the negative and positive data marks and the effects of noise can be reduced because a clock timer, for example, can be used to measure the duty ratio.

20

(Fifth alternative embodiment)

Fig. 33 shows the major components of a fifth alternative embodiment. While a discontinuity 86 is formed in the first wobble wave in the embodiment shown in Fig. 27, a mark 212 locally increasing the track groove  
25 width is formed in this embodiment shown in Fig. 33.

This mark 212 is used to detect the beginning of a sector block and is referred to as a block mark. The configuration shown in Fig. 33 does not produce a discontinuity interrupting the groove, and information other than the

VFO signal can therefore be recorded using block marks. As a result, overhead can be reduced.

(Sixth alternative embodiment)

5 Fig. 34 shows the major components of a sixth alternative embodiment. The variation shown in Fig. 34 forms a block mark 213 creating a local increase in groove wobble amplitude. Similarly to the variation shown in Fig. 33, this embodiment does not cause a discontinuity in the groove, and information other than the VFO signal can therefore be recorded using block  
10 marks.

(Seventh alternative embodiment)

Fig. 35 shows the major components of a seventh alternative embodiment. In this variation a wobble is formed only to one edge of the track  
15 groove. The preceding embodiments and variations apply particularly to so-called groove-recording optical discs that record data to the track groove, but there are also so-called land and groove optical discs that record data to both grooves and lands (the space between grooves) along the track. This seventh alternative embodiment of the invention applies to such land and groove type  
20 optical discs.

In the disc shown in Fig. 35 either negative data (0) (indicated by area 221) or positive data (1) (indicated by area 231) is recorded along one edge of the groove. This enables both the groove 2 and adjacent land 4 to be addressed by the same address. Data is recorded to both the land 4 and  
25 groove 2. This configuration enables the track pitch to be further reduced so that recording density can be further increased.

As will be known from the preceding description, the present invention forms a wobble of a specific shape and cycle in a unit period of the

track groove and records different shapes differing according to uniformly defined secondary information in said unit period. The present invention can therefore provide an optical disc medium that is suitable to high density recording, can record address information that reduces or eliminates overhead,  
5 and can generate a monotone wobble playback signal.
